Abstract

Injuries of the spinal cord often result in an irretrievable loss of motor and sensory functions of all body parts situated below the lesion site. Functional recovery is restricted mainly due to the limited regeneration and plasticity of injured axons in the adult central nervous system. Over the last few years different experimental approaches have led to axonal growth and functional benefits in animal models. This review focuses on the effects of the neutralization of myelin-associated neurite growth inhibitors, in particular Nogo-A, using the monoclonal antibody IN-1. Acute mAb IN-1 treatment of adult CNS lesioned rats results in extensive plastic changes of neuronal connections and regenerative fiber growth. In two different lesion paradigms (i.e. pyramidal tract lesion and incomplete spinal cord lesion in adult rats), the mAb IN-1-treated animals always showed a higher degree of recovery in various behavioral tests. These observations, together with electrophysiological results, suggest that neuronal CNS circuits of mAb IN-1-treated animals can be rearranged, and that sprouting and regenerating axons form functionally meaningful connections.

Theme: Development and regeneration

Topic: Motor systems

Keywords: Spinal cord injury; Myelin; Plasticity; Regeneration; Functional recovery; IN-1

Contents

1. Introduction

Patients suffering from an acute spinal cord injury (SCI) find themselves in an especially desperate situation, since severed axons of the central nervous system (CNS) are unable to regenerate spontaneously, and currently treatments to reestablish the lost neuronal connections are not available. It is difficult for a para- or tetra/quadraplegic patient to accept that two fully intact components of her/his body, 'the control unit' and 'the engine', namely the brain and the limbs, are irretrievably disconnected. For patients with a SCI, the present acute medical treatments focus on limiting the initial damage and on the management of bladder dysfunction, spasticity and neuropathic pain [24]. Functional recovery after a severe SCI is

restricted, and patients have to learn to make compensatory use of spared motor functions. After incomplete spinal cord injuries intensive physical therapy and to some extent functional electrical stimulation [66] are the only ways to improve the functional outcome. Regular locomotor training, by walking suspended on a treadmill, can even aid a certain group of patients to regain the capability of weight bearing and walking [21,22,93].

Early studies in animals have shown that injured CNS neurons are able to regrow neurites into peripheral nerve grafts [18]. Over the last 15 years, first promising steps were done to understand the factors involved in the lack of regeneration of neurites in the adult CNS tissue and, subsequently, to overcome some of the barriers for regeneration. Thus, encouraging progress is made towards the development of novel therapeutic approaches to treat spinal cord and brain injuries.

In this review, we will focus on the approach of neutralizing the neurite growth inhibitory activity associated with CNS myelin, in particular the protein Nogo-A [16], by the application of the monoclonal IN-1 antibody (mAb IN-1) [15].

2. Inhibition of neurite growth in the injured mammalian CNS

Despite clear differences in the regenerative potential of different CNS fiber populations, several experiments have rejected the view of an intrinsic inability of adult CNS fibers to regenerate. This crucial discovery was first made by Tello in 1911 [86], by offering central axons a transplanted piece of a peripheral nerve as a growth permissive substrate. Many years later, these experiments were confirmed [18,72] demonstrating irrevocably that the failure of CNS fibers to regenerate was not mainly due to intrinsic neuronal properties. The concept of a lack of neurotrophic support by the CNS was proposed and has been extensively investigated. Neurotrophic factors were shown to improve neuronal survival, sprouting and short distance growth within the lesioned central nervous system [35,43,48,69,75], but growing axons always avoided white matter.

The idea of neurite growth inhibition by CNS tissue was introduced in 1985 [80]. The very potent inhibitory nature of the CNS was attributed to a glial cell subtype: the myelinating oligodendrocytes [14,79,81]. This stands in contrast to the growth promoting properties of the Schwann cells of the peripheral nervous system [12]. Several myelin-associated proteins were shown to possess neurite growth inhibitory properties in vitro (Table 1): Nogo-A [16,78], MAG [51,59] and also certain chondroitin sulfate proteoglycans [25,61,85].

In addition to myelin, a barrier for nerve fibers to regenerate in the CNS which appears after an injury is the glial scar, forming a dense mechanical and probably biochemical barrier for growing axons at the lesion site. The scar consists of reactive astrocytes, microglia,

MAG, myelin associated glycoprotein; NGF, nerve growth factor; DRG, dorsal root ganglion; CSPG, chondroitin sulfate proteoglycans.

oligodendrocyte precursors, and often, fibroblasts. Furthermore, it contains several potentially repulsive and neurite growth inhibitory factors such as semaphorins, ephrins, tenascin and chondroitin sulfate proteoglycans [26,64,78].

3. Treatment approaches in animal models

For an optimal treatment to partially repair the lesioned CNS, the variety of barriers and inhibitory molecules will probably require a combination of different approaches [28,38,84]. Recently, experimental procedures have led to successful regeneration of injured fibers as well as anatomical reorganization of spared fiber systems. Such results were obtained by grafting peripheral nerve bridges [17], Schwann cells [46,97] or olfactory ensheathing cells [45,70] into the lesion site, as well as by the application of neurotrophic factors [35,43,69,75].

Regeneration of injured axons and increased sprouting of nerve cells by neutralizing or destroying myelin, thereby removing myelin-associated neurite growth inhibitors, has been achieved using various approaches (Table 1): the procedure to focally or transiently destroy myelin by X-radiation [74] or an immunological protocol, consisting of the combination of a myelin specific antibody and serum complement proteins resulted in chickens as well as in rats, in long distance regeneration of spinal axons [27,41,42,83]. A therapeutic approach to immunologically neutralize myelin-associated inhibitors in mice has been achieved by the vaccination with myelin components [39]. Also, this strategy resulted in a strong regenerative growth of a large number of CST axons.

In the case of the application of the mAb IN-1, extensive in vitro studies resulted in a significant neurite outgrowth on a CNS substrate [2,15,16,82]. The subsequent in vivo studies confirmed the in vitro results, in that lesioned adult corticospinal tract (CST) axons showed regenerative growth in adult rats, whenever the mAb IN-1 or an IN-1 Fab fragment were applied early following the SCI [7,8,76,77]. After 2 weeks of mAb IN-1 treatment, nerve fibers of the dorsally located CST showed sprouting of fibers around the lesion and scar tissue, and regenerative growth down the spinal cord up to distances of 10–20 mm. In the caudal spinal cord, the regenerated fibers formed dense arborizations suggesting their reconnection to the denervated spinal neuronal circuits [8]. Interestingly, the mAb IN-1 treatment after an CNS injury not only resulted in regenerative nerve fiber growth, it also enhanced sprouting and plastic growth of uninjured fibers at several levels of the motor system [67,87,100].

A major question arising from these studies is that of the functional significance of the observed regeneration and reorganization. It is widely assumed that a small number of preserved, regenerated or newly formed neuronal connections can have large functional impact [60], nevertheless, it is still unclear to which extent anatomical reintegration is needed to result in specific functional benefits. Guidance and target recognition cues have to be present or may have to be re-expressed in the adult and injured CNS, an appropriate amount of fibers has to invade the denervated targets, the fibers have to grow over sufficient distances, and mechanisms of adjustment and fine tuning of the new connections must be operative. To examine these issues, appropriate animal models have to be chosen to inflict a controlled and comparable injury and to quantify the various aspects of the behavioral outcome. Ideally, such models should allow correlating histological and electrophysiological findings with behavior, and they should be valid clinically. In a recent study such a correlation was made and compared with data of human SCI. It was found that the rat represents an adequate model for human SCI [53].

4. Monitoring functional recovery in animal models of spinal cord injury

Various animal models of SCI have been developed to answer injury specific questions (e.g. inflammation, regeneration, spasticity, etc.). In the field of SCI the rat has evolved as the animal of choice [6,55,57]. More recently, however, the availability of knockout and transgenic mice [4] strongly increased the interest for mouse models [40].

For anatomically complete SCI, two models have been developed: the complete transection model, in which the dura mater and the spinal cord are transected with a small blade or scissors, and the complete contusion model, in which a calibrated weight is dropped on to the spinal cord or the spinal cord is compressed by clips, resulting in a total local destruction of gray and white matter, but without lesion of the dura mater [5,96]. Models of complete SCI are particularly useful to examine the effects of implanted bridges and cell grafts [17,70], since they can provide clear evidence about regenerative fiber growth across the lesion.

Modeling incomplete spinal cord injuries can be achieved by different strategies. The first one consists of a mild or moderate contusion (weight drop model; [5]) or a compression [71] of the spinal cord without damaging the dura mater. Lesions obtained by such a technique mimic incomplete spinal cord lesions in humans. The use of graded impact/pressure intensity results in different degrees of destroyed gray and white matter. Typically, after a few days, cavities form at the lesion site, which are surrounded by scar tissue [78,84]. Alternative models are specific sections of defined tracts or funiculi with a fine blade, iridectomy scissors or by chemical ablation [7,8,50]. Such specific lesions have the advantage that single tract regeneration and/or reorganization can be monitored. They also allow a more precise behavioral testing, since specific and reproducible deficits occur. For a functional, behavioral analysis the appropriate testing strategy has to correspond to the specific lesion type chosen (Fig. 1). A

Fig. 1. Rat walking at constant speed on a treadmill. Video analysis allows reconstruction of the kinetics of hindlimb movement. Examples of an intact rat and an animal with a moderate spinal cord injury are shown.

dorsal lesion of the corticospinal tract will result, for example, in minor deficits of locomotion, but in persistent deficits of grasping or precise limb movements as detected when rats are walking on a grid [54,58]. Lesioning the lateral and ventral funiculi, including the reticulospinal tract and long descending propriospinal interneurons, results in more severe gait impairment [10,34,63].

In incomplete SCI usually spontaneous functional recovery occurs [47,62,89]. In animal models, prediction and quantification of the functional recovery following a specific type of lesion is of crucial importance to draw conclusions about a given experimental intervention. In case of mild injuries, spontaneous recovery is substantial, and the additional functions gained by an experimental intervention require testing paradigms of high resolution. The testing strategies should be adapted to the type and severity of the lesion, and time course studies should offer a transparent picture of the recovery process [6,40,55,57].

5. Mechanisms of spontaneous recovery

Different mechanisms with different time courses are involved in the spontaneous recovery processes, observed after SCI. A first stage represents the recovery of the so-called spinal shock [36,37,47]. Immediately after injury a complex cascade of biochemical reactions occurs in and around the lesion site, leading to ischemic tissue damage, axonal and myelin swelling, intracellular accumulation of Ca^{2+}, excessive release of the excitatory neurotransmitter glutamate and inflammatory processes [37,78]. These biochemical changes result in a phase of neuronal depression frequently associated with neuropraxia, i.e. a transient failure of axons to transmit impulses. The recovery of this phase is variable and lesion-dependent ranging, in rats, from hours to days [5].

An additional factor contributing to conductance failure of spinal cord tracts following injury is the demyelination of spared axons [78,90]. Spontaneous remyelination of these fibers can occur to some degree, and probably contributes to the functional recovery at later time points [32,73].

Important mechanisms of spontaneous functional recovery are adaptations, and plastic re-organizations of neuronal networks above and below the lesion [20,60,67]. Development of compensatory movement patterns has been observed for grasping after high cervical lesions [1,94] or for walking by involving axial muscles [33]. Another important mechanism for functional recovery represents the activity-dependent adaptation of spinal pattern generating networks; substantial recovery effects were obtained in cats and humans by specific training paradigms. Facilitation of stepping and weight bearing was obtained by regular treadmill training in spinal cats [3,19,49] but not in rats with incomplete SCI [29]. This training was also shown to be beneficial in patients with SCI [21,23,92]. In addition, spinal reflexes implicated in the control of stepping are involved in the recovery of stepping [30,65]. On the supraspinal level, rearrangements of cortical maps have been observed after spinal cord

injury in animals and humans [9,33,56]. In the spinal cord, sprouting of injured (Brosamle and Fouad, unpublished observation) and of uninjured CST fibers [91] to alternative targets has been shown, a process that may mediate the development of compensatory functional movement patterns.

6. Enhancing functional recovery by neutralizing neurite growth inhibitors

Adult CNS tissue, in particular CNS myelin, inhibit neurite growth in a variety of in vitro assays [51,59,79]. Various procedures to neutralize the inhibitory components of myelin have led to regeneration of lesioned axons and to functional changes in different models of spinal cord injury. The delay of myelination in developing chicken resulted in anatomical regeneration and functional recovery compared to that of embryos transected prior to the development of myelin. Also a transient disruption of myelin in the post-hatching chick, using a comparable approach, resulted in regeneration of brainstem projections. Although this did not promote functional recovery, electrophysiological examinations could demonstrate the reintegration of regenerated nerve fibers [41]. Also, a study using autovaccination against myelin in mice to promote axonal regeneration reported recovery in a functional test: Mice with anatomical evidence for regeneration of axons performed superior in the placing test, thereby indicating the reconnection of the CST [39].

Our laboratory has concentrated on the myelin-associated high molecular weight inhibitory protein NI-250/Nogo-A [15,16,81] and the effect of the monoclonal antibody IN-1 raised against this protein [15].

In two studies, an improved functional recovery after severe spinal cord injury followed by the application of mAb IN-1 over 2 weeks has been reported [7,52]. In both studies a dorsal spinal cord lesion was performed in adult rats at thoracic level (Th8). Control or IN-1 antibody producing hybridoma cells were implanted in the proximity of the ventricular system to allow constant diffusion of the antibodies into the entire CNS. The growth of the hybridoma cells was enabled by the application of cyclosporine over 5–7 days. Six weeks following a dorsal over-hemisection, stride length during walking and contact placing (a reflex known to depend on CST input in adults) significantly improved in the mAb IN-1-treated rats compared to the controls [7]. Pronounced sprouting and regeneration of CST fibers paralleled the improved functional recovery. A subsequent bilateral ablation of the motor cortex abolished the recovered contact placing.

In a subsequent study, a more detailed analysis of the locomotor behavior was performed [52]. Using the BBB open field locomotor score [6], significant improvement in the mAb IN-1-treated rats occurred over 2–4 weeks after the injury. Enhanced recovery was also observed in the grid walk test, as well as in the narrow beam test. The behavioral findings were confirmed by electromyographic examinations of muscle activity during treadmill walking, demonstrating the normalization of the stepping pattern in the mAb IN-1-treated rats (Fig. 2) [52]. The histological analysis of these animals showed that rats, especially with higher amounts of spared white matter, benefited from the mAb IN-1 treatment. Spared tissue functions as a bridge for regenerating fibers at the lesion site [8,77], but remaining fibers and tracts also represent the substrate for compensatory mechanisms. Indeed, studies with defined CST lesions at the level of the brain stem have shown that such compensatory processes can be greatly enhanced by mAb IN-1 application.

The transection of the pyramidal tract (CST) at the level of the brain stem, where it runs ventrally as a superficially located bundle, allows to deprive half or both sides of the spinal cord of its CST input without lesioning other tracts or the spinal cord itself. Such a lesion results in major and persistent deficits in the fine control of the paw and the digits [95]. A reliable and sensitive method to quantify these deficits is the grasping test where animals are trained to reach for food pellets [87,94]. To test the effect of mAb IN-1, control or IN-1 antibody producing hybridoma cells were implanted into the hippocampus of adult rats that had undergone a unilateral lesion of the pyramidal tract. In the mAb IN-1-treated animals, this resulted in sprouting of cortico-bulbar fibers and establishment of bilateral cortico-rubral and cortico-pontine projections [87,100], similar to those observed in neonatally lesioned rats [99]. In the spinal cord the remaining CST sprouted across the midline [87]. The anatomical rearrangements were associated with an almost complete functional recovery in the food pellet grasping test [87]. Although limited regeneration of the CST occurred at the lesion site [68] a re-lesioning of these fibers did not disrupt the recovery. This indicates that the improved function was due to compensatory sprouting and plastic rearrangements [100]. Plasticity can also involve fiber systems that are untouched by a lesion, as shown in a study where the pyramidal tract was lesioned bilaterally in adult rats, followed by a control or mAb IN-1 treatment [67]. Whereas control animals (lesion only or lesion with control antibody) showed severe impairments in the grasping test, the mAb IN-1-treated rats recovered to prelesion levels. Anatomically, the rubrospinal tract was observed to increase the number of collaterals in the cervical spinal cord (by more than 100%). These fibers projected to the deep ventral horn, possibly replacing the lost CST fibers [67]. Microstimulation of the forelimb area of the motor cortex in mAb IN-1-treated rats induced EMG responses in the forelimbs, which were never observed in control-Ab-treated rats. These responses were abolished by injection of the GABA receptor agonist muscimol into the red nucleus, showing the presence of a new, cortico-rubro-spinal pathway induced by the mAB IN-1 treatment.

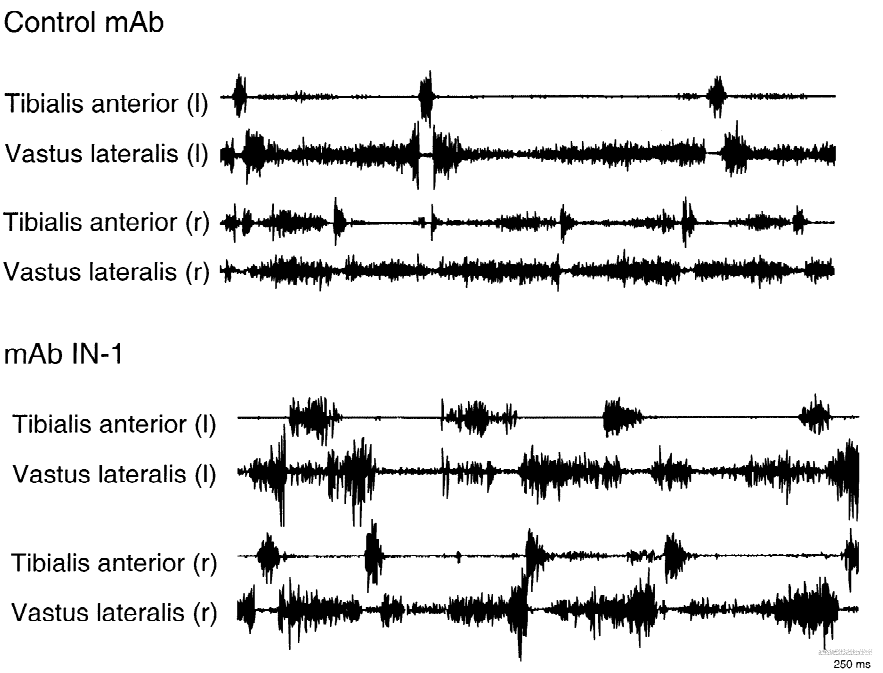

Fig. 2. EMG activity of two representative examples of spinal cord lesioned rats treated with a control antibody (hybridoma transplant) (top) or IN-1 antibodies (bottom). Typical abnormalities in the control animal are the uncoupling of left and right tibialis anterior. Animals treated with mAb IN-1 show a much more normal walking pattern with correct left–right alteration and good flexor–extensor alteration (for details see Ref. [52]; courtesy of Dr D. Merkler, Zürich).

Plastic effects of the mAb IN-1 and of new anti Nogo-A antibodies on intact fiber systems were also observed in the intact adult cerebellum, where Purkinje cells upregulated immediate early genes [98], and grew nodal sprouts along their axons [11], in response to these antibodies. Together these results suggest that the Nogo-A protein acts not only as a growth inhibitor for injured axons, but also as a general regulator for neuronal growth and a stabilizing factor for the complex adult neuronal network.

7. Neutralization of growth inhibitors — a way to the clinic?

Several important requirements have to be fulfilled before treatments that enhance fiber regeneration and plasticity can be clinically applied. In the case of antibodies against the potent neurite growth inhibitors like Nogo-A, the first requirement is an appropriate antibody administration procedure. The antibody production by implanted hybridoma cells does not allow a controlled application. A major step towards a more defined treatment strategy was the cloning of Nogo, which allows to produce specific antibodies against various regions of the Nogo protein and to design strategies for the cloning of Nogo-A receptors [16,31]. Several antibodies against rat or human Nogo are currently being tested in vivo and in vitro. Application of the purified antibodies via pumps will allow a very controlled application, which can be expanded to weeks or months. It is likely that such a prolonged treatment will result in prolonged and more robust regeneration and sprouting of injured and uninjured nerve fibers. This may result in increased functional benefits especially when long distance regeneration is necessary like in the injured spinal cord. However, long-term application of antibodies might also include certain dangers. Although, no negative side effects of the mAb IN-1 treatment have been detected so far [52], it remains a highly important question whether sprouting and regenerative growth of nerve fibers (including sensory fibers) can result in improper connections leading to malfunctions. Effects of long-term suppression of growth inhibitors on circuits and functions, and the specific role of neuronal activity and training for newly formed connections have to be studied in future experiments.

Another important step towards a clinical application is the demonstration of increased plasticity and regenerative growth due to Nogo-A neutralization in a mammalian species closer to man than rodents. This is currently under investigation in our laboratory in monkeys, using specific lesions of the CST in the spinal cord and studying the deficits in hand and leg function and their recovery.

To optimize the functional recovery after a spinal cord injury, the anti Nogo-A treatment probably has to be combined with additional neurite growth promoting approaches. To overcome caverns and the scar, a combination with a bridging strategy like Schwann cell, olfactory ensheathing glia or stem cell transplants [38,45,70,97]

could be of interest. The application of growth promoting factors like NT-3 has already proven to have additive growth enhancing effects [35,38,75]. For the long-term future, a well-balanced combination of such approaches may have to be specifically and individually designed for each patient according to lesion type and extent and the specific functional profile.
